## Abstract

This work presents a methodology to address the problems of bubbles and drops evolving in incompressible, viscous flows due to the effect of surface tension. It is based on the combination of a recently developed immersed interface method to resolve discontinuities, with the level set (LS) method to reproduce the evolving interfaces. The paramount feature of this immersed interface method is the use of Lagrange interpolation enclosing grid points positioned in the vicinity of the interface and few exceptional grid points positioned on the interface. Different problems are considered to assert the accurateness of the proposed methodology, involving both simple and complex interface geometries. Precisely, the following problems are addressed: circular flow with a fixed interface, the dispersion of capillary waves, initially circular, ellipse, star shaped bubbles oscillating to an equilibrium state, and circular drops deforming in shear flows. The transient evolution of bubbles/drops in terms of their shapes, pressure profiles, velocity vectors, deformation ratios of major and minor axis is analyzed to observe the effect of surface tension. The proposed methodology is seen to recover the exact numerical equilibrium between the surface tension and pressure gradient in the vicinity of complex interface geometries as well, while recreating the flow physics with an adequate level of accuracy with well representation of overall trends. Moreover, the numerical results yield a good level of agreement with the reference data.

## 1 Introduction

Recently, there is a growing interest to model and simulate the behaviour of liquid drops or gas bubbles that are immersed in viscous fluids. These studies are motivated by the presence of multiple fluid environments in daily life and by numerous scientific and engineering applications. Examples are fluid mixing, fuel injection in engines, bubble column reactors, particulate flows, suspension rheology, biofluid-dynamics such as emulsion rheology, blood flow, to name only a few. To cite another example, deformation and cleavage of cells generally involves multiple drop deformation processes (Greenspan, 1977a, 1977b; Li and Lubkin, 2001). Moreover, some emerging and rapidly growing technologies like digital microfluidics are fed from the knowledge of the topology of drop or bubbles evolving through microgeometries (Stone et al., 2004). Since the shape and

size of the droplet determine important properties such as stability, rheology, and particle morphology, it is important to understand the mechanism of bubble deformation, growth, and breakup. The success in numerical simulations of these flows lies in the capability of numerical algorithm to address the following dominant issues:

- The fluid interfaces must be accurately computed and well represented.
- Discontinuity of material properties (e.g., density, viscosity) across these interfaces must be effectively treated while accounting for the forces acting on them like surface tension.
- The computations should be stable while having advantages like easy implementation, low in time and cost.

In order to address the first issue, two main groups of numerical techniques have been developed in the literature. Namely, Lagrangian methods (e.g., front tracking (Unverdi

✉ hvrmittal@gmail.com

and Tryggvason, 1992)) and Eulerian methods (e.g., the level set (LS) (Osher and Sethian, 1988; Chang et al., 1996), the Volume-of-Fluid (VOF) methods (Scardovelli and Zaleski, 1999; Ketterl et al., 2019; Klein et al., 2019)). The location of the interface is explicitly known in Lagrangian methods and consequently the implementation of surface tension and interfacial boundary conditions is straight forward. However, a major shortcoming of this method is that once the interface topology starts varying, “surgical” procedures are required to smooth and distribute the interfacial elements utilized to represent the interface (Raessi et al., 2010). Such procedures are complicated when interfaces merge or split, specifically in three dimensions (3D) (Osher and Fedkiw, 2006). On the other hand, in Eulerian methods, the location of an interface is implicitly represented by a scalar function in general on a Eulerian mesh, which serves as an indicator and as such it permits interfaces to merge or break with relative ease. The interface is allowed to evolve on a fixed numerical mesh by solving an advection equation involving this indicator function (for example, the LS function or the VOF function). The methodology proposed in the present work considers a set of governing equations with the interfacial conditions embedded in the field equations as source terms. The equations are discretized in a finite-thickness interfacial zone, within which the fluid properties change smoothly (Chang et al., 1996). This approach has been undertaken along with the application of the LS method for modelling the interfaces. The LS method introduced in Osher and Sethian (1988) is a numerical approach for implicitly evolving the interface by means of a smooth (Lipschitz continuous) function (denoted by  $\phi$ ) defined on the entire physical domain. By initializing the interface as the zero level set of this function, the interface propagates naturally with the evolution of zero level set. Some of its advantages over other methods include its ability to easily handle topological changes like breakup and merging, well generalization to three dimensions, and its relatively easy implementation.

The Navier–Stokes equations for incompressible viscous flows constitute a mainstay for computing multiphase flows. The numerical methodology adopted herein is the classic Chorin pressure projection scheme (Chorin, 1967). This method consists of splitting the solution procedure into distinct steps in which the velocity and pressure are decoupled by introducing a pressure Poisson equation. A literature survey reveals the existence of many numerical studies related to the modifications of this method, for example, Balcázar et al. (2016), Chakraborty et al. (2013), Francois and Shyy (2003), Francois et al. (2006), Hysing (2012), Huang et al. (2015), Li and Lai (2001), LeVeque and Li (1997), Mier-Torrecilla et al. (2011), Tong and Wang (2007), Uh and Xu (2012), and the references therein. However all these variants of the projection method are fraught with certain

shortcomings, mostly with evaluating pressure, for instance, oscillations in the pressure profile in the vicinity of the interface (Mier-Torrecilla et al., 2011; Balcázar Arciniega, 2014). Additionally, it is vital to accurately compute interfacial quantities such as curvature and normal vectors because they are used to evaluate the surface tension force. Numerical imbalance of the surface tension force and the associated pressure gradient is likely to induce non physical velocities, commonly known as spurious or parasitic currents (Raessi et al., 2010; Hysing, 2012; Balcázar et al., 2016). These currents can flourish with time and can degrade simulation results significantly. In particular, one has to be extremely careful in ascertaining that the interface topologies projected by computation are not numerical artifacts arising from errors.

In the present paper, a coupling between LS and a recently developed higher order accurate immersed interface method (Mittal and Ray, 2018) has been proposed to address the problems of drops or bubbles evolving in incompressible, viscous flows due to surface tension force. The paramount feature of this immersed interface scheme is the use of Lagrange interpolation enclosing adjacent grid points and few special grid points named as “the interfacial points” as nodes. Interfacial points are defined as points in the domain where grid lines intersect the interface. The use of this methodology in conjunction with the LS method allows us to deal with intricate interface geometries with a very simple mesh generation process. For a fixed interface, this methodology has been thoroughly validated in one, two, and three dimensions (Mittal and Ray, 2018). In the present work, this methodology is extended to solve moving interface problems governed by N-S equations for the first time. Following problems are considered to assert the accurateness of proposed methodology: dispersion of capillary waves for validation, circular flow with a fixed interface; static circular bubble at equilibrium in a fluid at rest, initially ellipse shaped and star shaped bubbles oscillating to an equilibrium state, and drops deforming in shear flows. The proposed methodology is found to proficiently recreate the flow physics with an adequate level of accuracy with well representation of overall trends and the results are in good agreement with those in the literature.

The paper is arranged in the following sequence: Section 2 presents the mathematical formulation of the proposed methodology. Its numerical treatment is addressed in Section 3 followed by the numerical examples in Section 4. At the end, the observations are summarised in the conclusion in Section 5.

## 2 Mathematical formulation

The mathematical formulation of the proposed methodology is presented in the present section. The equations depicting

the conservation of mass and momentum of two unsteady, viscous, incompressible, immiscible fluids are given by the Navier–Stokes equations defined on a spatial domain  $\Omega$  with boundary  $\partial\Omega$  as (Chang et al., 1996):

$$\rho_i \left( \frac{\partial \mathbf{u}_i}{\partial t} + \mathbf{u}_i \cdot \nabla \mathbf{u}_i \right) = \nabla \cdot \mathbf{S}_i + \rho_i \mathbf{g} \quad (1)$$

$$\mathbf{S}_i = -p_i \mathbf{I} + \mu_i (\nabla \mathbf{u}_i + (\nabla \mathbf{u}_i)^T) \quad (2)$$

and

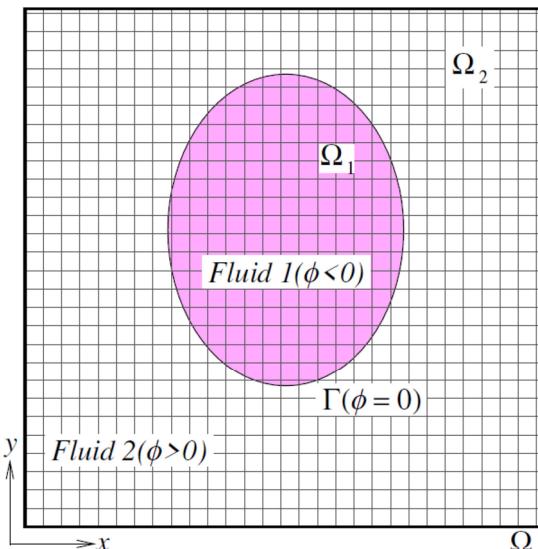

$$\nabla \cdot \mathbf{u}_i = 0 \quad (3)$$

where  $t$  is the time,  $\rho$  is the density,  $\mu$  is the viscosity,  $p$  is the pressure,  $\mathbf{u} = (u, v)$  is the velocity field,  $\mathbf{g}$  is the acceleration due to gravity,  $\mathbf{S}$  is the stress tensor,  $\mathbf{I}$  is the identity tensor, and the super-index T represents the transpose operator. Figure 1 shows an illustration of a square domain  $\Omega$  embedded with an interface  $\Gamma$  separating two immiscible fluids. The apex  $i = 1, 2$  represents variables correlating to the regions labelled as fluid 1 and fluid 2 (see Fig. 1) respectively. Assuming no mass transfer between the fluids yields a continuous velocity condition at the interface:

$$\mathbf{u}_1 = \mathbf{u}_2 \text{ at } \Gamma \quad (4)$$

The effect of surface tension is to balance the jump of the normal stresses along the fluid interface. Overlooking the variations of the surface tension coefficient,  $\sigma$  gives the following boundary condition for momentum conservation at the interface (Chang et al., 1996; Balcazar et al., 2016):

$$(\mathbf{S}_1 - \mathbf{S}_2) \cdot \mathbf{n} = \sigma \kappa \mathbf{n} \text{ at } \Gamma \quad (5)$$

**Fig. 1** Illustration of a computational domain,  $\Omega$  showing the evolution of a level set function,  $\phi(\mathbf{x}, \mathbf{y})$  with a zero contour marking the interface,  $\Gamma$ .

where  $\mathbf{n}$  is a unit outward normal vector along  $\Gamma$ . The resulting evolution equations can be mingled into a set of equations for a single fluid in  $\Omega$ , with the effect of surface tension in terms of a singular source term (Balcazar et al., 2016):

$$\rho \left( \frac{\partial \mathbf{u}}{\partial t} + \mathbf{u} \cdot \nabla \mathbf{u} \right) = -\nabla p + \nabla \cdot [\mu (\nabla \mathbf{u} + \nabla \mathbf{u}^T)] + \rho \mathbf{g} + \sigma \kappa \mathbf{n} \delta_\Gamma \quad (6)$$

$$\nabla \cdot \mathbf{u} = 0 \quad (7)$$

where  $\delta_\Gamma$  is the Dirac delta function (ensuring that  $\sigma$  is only applied at the location  $\Gamma$ ).

## 2.1 Interface capturing

The position of the interface is evolved in time using the LS method, introduced in Osher and Sethian (1988). A smooth level set function  $\phi(\mathbf{x}, t)$  is defined over  $\Omega$  in such a way that  $\phi > 0$  in one fluid region (i.e., in  $\Omega_2$ ) and  $\phi < 0$  in the other fluid region (i.e., in  $\Omega_1$ ) and the interface position is characterized by  $\phi = 0$ . The time evolution of the interface is obtained solving the Hamilton–Jacobi equation for  $\phi$ :

$$\frac{\partial \phi}{\partial t} + \mathbf{u} \cdot \nabla \phi = 0 \quad (8)$$

At each time,  $t$ , the fluid domain  $\Omega_i$  are defined by the sign of  $\phi$  and the parameters required to impose the jump conditions at the interface  $\Gamma$  are obtained from the level set function  $\phi(\mathbf{x}, t)$ . For some problems, a source term is added to right hand side of Eq. (8) to maintain the mass conservation in the solution process (Yuan et al., 2018). This source term is the difference between the current mass at each time step during the solution process and the initial mass.

The accurate computation of the curvature,  $\kappa$  and the normal,  $\mathbf{n} = \nabla \phi / |\nabla \phi|$  desires the values of  $\phi$  to be nearly a signed distance function, that is  $|\nabla \phi| = 1$ . The numerical solution of Eq. (8) rapidly loses the signed distance property during larger time computations, thus a correction is introduced solving the so-called re-initialization equation (Sussman et al., 1994) for few steps in the pseudo-time  $\Theta$ :

$$\frac{\partial \phi}{\partial \Theta} + S(\phi_0)(|\nabla \phi| - 1) = 0 \quad (9)$$

The operator  $S(\phi_0) = \phi_0 / \sqrt{\phi_0^2 + h}$  is a smoothed sign function,  $\phi_0 = \phi(\Theta = 0)$  is the initial zero level set function and  $h$  is the grid spacing.

## 2.2 Surface tension treatment

Implementation of a pertinent surface tension model is

necessary for an accurate calculation of curvature and incorporation of pressure jump into the fluid domain. By the means of  $\phi$ , the singular source term,  $\sigma\kappa\delta_\Gamma$  in Eq. (6) can be expressed as (Chang et al., 1996; Gutiérrez et al., 2018):

$$\sigma\kappa\delta_\Gamma = \sigma\kappa\delta(\phi)\nabla\phi \quad (10)$$

The curvature  $\kappa$  can be expressed in terms of  $\phi$  and its derivatives as

$$\kappa(\phi) = \frac{\phi_y^2\phi_{xx} - 2\phi_x\phi_y\phi_{xy} + \phi_x^2\phi_{yy}}{(\phi_x^2 + \phi_y^2)^{3/2}} \quad (11)$$

### 2.3 Governing equations

This conversion of the singular source term in Eq. (10) enables us to reformulate the evolution equations (6) and (7) as

$$\rho\left(\frac{\partial\mathbf{u}}{\partial t} + \mathbf{u}\cdot\nabla\mathbf{u}\right) = -\nabla p + \nabla\cdot[\mu(\nabla\mathbf{u} + \nabla\mathbf{u}^\top)] + \rho\mathbf{g} + \sigma\kappa(\phi)\delta(\phi)\nabla\phi \quad (12)$$

and

$$\nabla\cdot\mathbf{u} = 0 \quad (13)$$

All quantities in the above-mentioned equations are made dimensionless using the following reference values:

$$\begin{aligned} \tilde{x} &= \frac{x}{L}, \tilde{u} = \frac{u}{U}, \tilde{t} = \frac{tU}{L}, \tilde{p} = \frac{p}{\rho_{\text{ref}}U^2}, \tilde{\mathbf{g}} = \frac{\mathbf{g}}{g_{\text{ref}}} \\ \tilde{\rho} &= \frac{\rho}{\rho_{\text{ref}}}, \tilde{\mu} = \frac{\mu}{\mu_{\text{ref}}} \end{aligned}$$

where  $L$  is the characteristic length scale; the subscript ref is for the reference values being equal to the values of phase in domain  $\Omega_2$ . Therefore, the dimensionless forms of Eqs. (12) and (13), in which the superscripts  $\sim$  are omitted for convenience, are

$$\begin{aligned} \rho\left(\frac{\partial\mathbf{u}}{\partial t} + \mathbf{u}\cdot\nabla\mathbf{u}\right) &= -\nabla p + \frac{1}{Re}\nabla\cdot[\mu(\nabla\mathbf{u} + \nabla\mathbf{u}^\top)] \\ &+ \frac{1}{Fr}\rho\mathbf{g} + \frac{1}{We}\kappa(\phi)\delta(\phi)\nabla\phi \end{aligned} \quad (14)$$

$$\nabla\cdot\mathbf{u} = 0 \quad (15)$$

where  $Re$  is the Reynolds number,  $We$  is the Weber number, and  $Fr$  is the Froude number, defined as

$$Re = \frac{\rho_{\text{ref}}UL}{\mu_{\text{ref}}}, \quad We = \frac{\rho_{\text{ref}}U^2L}{\sigma}, \quad Fr = \frac{U^2}{g_{\text{ref}}L}$$

Since physical properties change discontinuously across the interface, a Heaviside function,  $H$  is utilized to distinguish

these fluid properties in each domain, yielding the following equations:

$$\rho = \lambda + (1-\lambda)H, \quad \mu = \eta + (1-\eta)H$$

where  $\lambda = \rho_1 / \rho_2$  is the density ratio,  $\eta = \mu_1 / \mu_2$  is the viscosity ratio, and the value of  $H$  is equal to one in  $\Omega_1$  and zero elsewhere.

The sharp changes in these physical properties across the interface  $\Gamma$  can pose numerical difficulties (Chang, et al., 1996; Gutiérrez et al., 2018). In order to resolve these issues, the interface is given a fixed thickness  $\varepsilon$  proportional to mesh spacing  $h$ . Firstly, a regularization for  $\delta$  is introduced using  $H$ . Following Peskin (1977), the regularized delta function,  $\delta_\varepsilon$  (where  $\varepsilon$  is typically set to some integral or fractional multiple of  $h$ ) is defined as

$$\delta_\varepsilon(\phi) = \begin{cases} \frac{1}{2}\left(1 + \cos\left(\frac{\pi\phi}{\varepsilon}\right)\right)/\varepsilon, & \text{if } |\phi| < \varepsilon \\ 0, & \text{elsewhere} \end{cases}$$

$H_\varepsilon$  is defined as

$$H_\varepsilon(\phi) = \begin{cases} 0, & \text{if } \phi < -\varepsilon \\ (\phi + \varepsilon)/(2\varepsilon) + \sin\left(\frac{\pi\phi}{\varepsilon}\right)/(2\pi), & \text{if } |\phi| \leq \varepsilon \\ 1, & \text{if } \phi > \varepsilon \end{cases}$$

The above Heaviside function satisfies the relation  $\frac{dH_\varepsilon(\phi)}{d\phi} = \delta_\varepsilon(\phi)$ . Using  $H_\varepsilon$ , the corresponding regularized viscosity,  $\mu_\varepsilon$  and regularized density,  $\rho_\varepsilon$  can be written as follows:

$$\rho_\varepsilon = \lambda + (1-\lambda)H_\varepsilon(\phi) \quad (16)$$

$$\mu_\varepsilon = \eta + (1-\eta)H_\varepsilon(\phi) \quad (17)$$

With this regularisation, the resulting equations (1)–(3) are well posed (Chang et al., 1996), written as follows:

$$\begin{aligned} \rho_\varepsilon\left(\frac{\partial\mathbf{u}}{\partial t} + \mathbf{u}\cdot\nabla\mathbf{u}\right) &= -\nabla p + \frac{1}{Re}\nabla\cdot[\mu_\varepsilon(\nabla\mathbf{u} + \nabla\mathbf{u}^\top)] \\ &+ \frac{1}{Fr}\rho_\varepsilon\mathbf{g} + \frac{1}{We}\kappa\delta_\varepsilon\nabla\phi \end{aligned} \quad (18)$$

$$\nabla\cdot\mathbf{u} = 0 \quad (19)$$

### 2.4 Interface jump conditions

The interface normal velocity jump condition, in absence of mass transfer, can be written as

$$[\mathbf{u}] \cdot \mathbf{n} = 0 \quad (20)$$

where the operator  $[\mathbf{u}] = u_2 - u_1$  at  $\Gamma$  and  $\mathbf{n} = (n_1 \ n_2)^\top$  is the interface normal unit vector. Enforcing the no-slip

condition at the interface, the tangential velocity jump condition can be written as

$$[\mathbf{u}] \cdot \mathbf{t} = 0 \quad (21)$$

where  $\mathbf{t}$  is the interface tangent unit vector. Combining Eqs. (20) and (21), the velocity jump condition at the interface is  $[\mathbf{u}] = 0$ . Integrating Eq. (18) across  $\Gamma$  and considering the effects of the surface tension, the following stress jump condition is obtained:

$$[\bar{\mathbf{T}}] \cdot \mathbf{n} - \sigma \mathbf{n} (\nabla \cdot \mathbf{n}) = 0 \quad (22)$$

where  $\sigma$  is the constant surface tension,  $-\nabla \cdot \mathbf{n} = \kappa$ , the interface curvature and  $\bar{\mathbf{T}} \cdot \mathbf{n}$  is the stress tensor. In this case the non-uniform surface tension contribution  $\nabla \sigma$  is neglected, thus the tangential stress component jump  $(\bar{\mathbf{T}} \cdot \mathbf{n}) \cdot \mathbf{n} = 0$ . For a Newtonian fluid, the interface normal component of the jump condition (22) yields:

$$\left[ p - 2\mu \frac{\partial \mathbf{u} \cdot \mathbf{n}}{\partial \mathbf{n}} \right] = \sigma \kappa \quad (23)$$

Equation (23) can be rewritten as follows:

$$[p] - 2[\mu] \frac{\partial \mathbf{u} \cdot \mathbf{n}}{\partial \mathbf{n}} = \sigma \kappa \quad (24)$$

where  $[p] = p_2 - p_1$  at  $\Gamma$  and  $[\mu] = \mu_2 - \mu_1$  at  $\Gamma$ .

### 3 Numerical method of solution

The set of governing equations (18) and (19) posed in Section 2.3 are discretized on a uniform Cartesian grid. Without loss of generality, the solution domain,  $\Omega$  is considered to be a rectangle with a curved interface,  $\Gamma$  (see Fig. 1). The governing equations are solved by the means of standard projection method (Chorin, 1967), which comprises of three different steps. In the first step, an intermediate velocity,  $\mathbf{u}^*$  is computed explicitly by ignoring the pressure gradient term:

$$\rho_\varepsilon^n \left( \frac{\mathbf{u}^* - \mathbf{u}^n}{\Delta t} + \mathbf{u}^n \cdot \nabla \mathbf{u}^n \right) = \frac{1}{Re} \nabla \cdot [\mu_\varepsilon^n (\nabla \mathbf{u} + \nabla \mathbf{u}^\top)] + \frac{1}{Fr} \rho_\varepsilon^n \mathbf{g} + \frac{1}{We} \kappa \delta_\varepsilon \nabla \phi \quad (25)$$

The superscript,  $n$  denotes the quantities at  $n$ -th time level. In this equation (projector step), the diffusion terms are discretized by using the standard central difference scheme. However, the convection terms are discretized by means of a second order ENO scheme. In the second step of the method, to satisfy the incompressibility constraint,  $\nabla \cdot \mathbf{u}^{n+1} = 0$ , the pressure at  $(n+1)$ -th time level,  $p^{n+1}$  is defined through the solution of Poisson equation:

$$\nabla^2 p^{n+1} = \frac{\rho_\varepsilon^{n+1}}{\Delta t} \nabla \cdot \mathbf{u}^* \quad (26)$$

Numerical solution of the pressure Poisson equation (26) is challenging due to the discontinuities in the variables near the interface. To compute pressure, an efficient immersed interface scheme is enforced, according to Mittal and Ray (2018). The detailed discussion of this scheme is presented in Section 3.1.

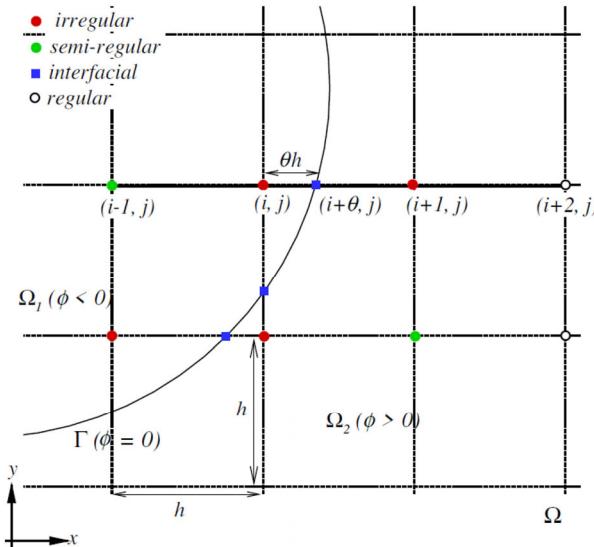

The final step of the method is to compute the velocity field at  $(n+1)$ -th time level,  $\mathbf{u}^{n+1}$  from the following expression:

$$\mathbf{u}^{n+1} = \mathbf{u}^* - \frac{\Delta t}{\rho_\varepsilon^{n+1}} \nabla p^{n+1} \quad (27)$$

The set of Eqs. (25)–(27) comprise to form a N-S solver which are simulated along with the application of LS method to reproduce the evolving interfaces. Third order accurate TVD Runge Kutta scheme is enforced to solve the LS advection equation (8) and the reinitialisation equation (9) in time. Spatial discretization in the LS method is carried out by using a fifth order HJ-WENO scheme.

#### 3.1 Immersed Interface treatment

In order to discretize Eq. (26), the grid points in the computational domain are categorized into regular and irregular points (Mittal, 2016; Mittal et al., 2016; Mittal and Ray, 2018). A grid point is said to be an grid irregular point, if the finite difference stencil resulting from the approximation of the derivatives encloses points from both sides of  $\Gamma$ . Otherwise, they are categorized as regular. Our numerical algorithm is based upon enforcing a nine point HOC scheme (Mittal et al., 2016, 2017a, 2017b; Mittal and Al-Mdallal, 2018) for discretization at regular points and a higher order accurate immersed interface method at the irregular points. However, as we contemplate on using a nine point HOC scheme on the regular points, if all the eight neighbours of a regular point cannot be found on the same side across  $\Gamma$ , there is a need for redefining such regular points. Subsequently, we further classify a regular point as “semi-regular” (labelled in Fig. 2). A regular point in the subdomain  $\Omega_i$  is termed as semi-regular if at least one of its eight neighbouring points in the nine point HOC stencil belongs to  $\Omega_j$  such that  $i \neq j$ ,  $i, j = 1, 2$ . The methodology employed at irregular points curtails to standard central differences at semi-regular points. The detailed description of the methodology used for the discretization of Eq. (26) at irregular points is presented. The paramount feature of this methodology is the use of interfacial points as nodes in the stencil, which allows us to employ standard finite difference approximations directly. Pertinent interpolation

**Fig. 2** Illustration of the magnified view of computational domain,  $\Omega$  in the vicinity of the interface,  $\Gamma$ . Different classifications of grid points are highlighted with coloured symbols and a general interpolation stencil used in our computations is outlined.

techniques are enforced on both sides of the interface to determine the values at interfacial points. Figure 2 sketches a magnified view of  $\Omega$  in the vicinity of  $\Gamma$ . It outlines different classifications of grid points, along with a general interpolation stencil used for computations.

Let  $(x_i, y_j)$  be an irregular grid point (see Fig. 2). The discretization at irregular points follows the similar procedure in both  $x$  and  $y$ -directions. Therefore, the modified formulas are presented only in  $x$ -direction on the segment  $[x_{i-(N-1)}, x_{i+M}] \times \{y_j\}$  and the subscript  $j$  in the notations below is omitted. Denote the interfacial point by “ $x_{i+\theta}$ ” such that

$$x_{i+\theta} = x_i + \theta h, \quad 0 < \theta < 1$$

Denoting the approximation at point  $x_i$  by  $p_i$ , the central difference formula for the derivative  $\frac{\partial^2 p}{\partial x^2}$  enclosing grid points  $x_{i-1}$ ,  $x_i$ , and the interfacial point  $x_{i+\theta}$  as nodes can be written as

$$\left. \frac{\partial^2 p}{\partial x^2} \right|_i \approx \left( \frac{p_{i+\theta}^- - p_i - p_i - p_{i-1}}{x_{i+\theta} - x_i} - \frac{p_i - p_{i-1}}{x_i - x_{i-1}} \right) / \left[ \frac{(x_{i+\theta} - x_i) + (x_i - x_{i-1})}{2} \right] \quad (28)$$

We now introduce the notation  $p_{i+\theta}^-$  to denote the value of  $p$  at the interfacial point  $x_{i+\theta}$  in  $\Omega_1$ . Correspondingly,  $p_{i+\theta}^+$  denotes the value of  $p$  at the interfacial point  $x_{i+\theta}$  in  $\Omega_2$ .  $p_{i+\theta}^-$  is calculated by Lagrange polynomial interpolation by using points on both sides of the interface and the interfacial point. The interpolating polynomial on one side of the interface enclosing  $(N+1)$  points  $\{x_{i-(N-1)}, \dots, x_{i-1},$

$x_i, x_{i+\theta}\}$  can be written as

$$L^-(x) = \sum_{k=-(N-1)}^0 l_k(x) u_{i+k} + l_\theta(x) u_{i+\theta}^- \quad (29)$$

Similarly, the interpolating polynomial on the other side of interface enclosing  $(M+1)$  points  $\{x_{i+\theta}, x_{i+1}, x_{i+2}, \dots, x_{i+M}\}$  can be written as

$$L^+(x) = \sum_{k=1}^M h_k(x) u_{i+k} + h_\theta(x) u_{i+\theta}^+ \quad (30)$$

Here  $l_k(x)$  and  $h_k(x)$  are the Lagrange basis polynomials and they are respectively given by

$$l_k(x) = \prod_{\substack{-(N-1) \leq l \leq 0, l=\theta \\ l \neq k}} (x - x_{i+l}) / \prod_{\substack{-(N-1) \leq l \leq 0, l=\theta \\ l \neq k}} (x_{i+k} - x_{i+l})$$

and

$$h_k(x) = \prod_{\substack{l=\theta, 1 \leq l \leq M \\ l \neq k}} (x - x_{i+l}) / \prod_{\substack{l=\theta, 1 \leq l \leq M \\ l \neq k}} (x_{i+k} - x_{i+l})$$

Differentiating polynomial equations (29) and (30) term by term and substituting into derivative jump condition ( $[p_x]_\Gamma$ ) at the interface yield:

$$\left[ \sum_{k=1}^M h'_k(x_{i+\theta}) p_{i+k} + h'_\theta(x_{i+\theta}) p_{i+\theta}^+ \right] - \left[ \sum_{k=-(N-1)}^0 l'_k(x_{i+\theta}) p_{i+k} + l'_\theta(x_{i+\theta}) p_{i+\theta}^- \right] = [p_x]_\Gamma \quad (31)$$

Note that derivative jump conditions are nothing but the derivative of Eq. (24) in the direction normal to the interface. Equation (31) is a discretized version obtained by resolving the normal jump along  $x$ -direction. It is easy to see that jump relation (24) translates to

$$p_{i+\theta}^+ - p_{i+\theta}^- = [p]_\Gamma \quad (32)$$

so that Eqs. (31) and (32) simplify to

$$\begin{bmatrix} h'_\theta(x_{i+\theta}) & -l'_\theta(x_{i+\theta}) \\ 1 & -1 \end{bmatrix} \begin{bmatrix} p_{i+\theta}^+ \\ p_{i+\theta}^- \end{bmatrix} = \begin{bmatrix} b_1 \\ b_2 \end{bmatrix} \quad (33)$$

where

$$b_1 = [p_x]_\Gamma - \left\{ \sum_{k=1}^M h'_k(x_{i+\theta}) - \sum_{k=-(N-1)}^0 l'_k(x_{i+\theta}) \right\} p_{i+k}$$

and

$$b_2 = [p]_\Gamma$$

Solution of Eq. (33) yields the following general formula for  $p_{i+\theta}^-$ :

$$p_{i+\theta}^- = \frac{1}{D} \left\{ \sum_{k=-N+1}^M a_k p_{i+k} + [p_x]_\Gamma - h'_\theta(x_{i+\theta}) [p]_\Gamma \right\} \quad (34)$$

where

$$D = h'_\theta(x_{i+\theta}) - l'_\theta(x_{i+\theta})$$

$$a_k = \begin{cases} l'_k(x_{i+\theta}), & k = -(N-1), \dots, 0 \\ h'_k(x_{i+\theta}), & k = 1, \dots, M \end{cases}$$

The same procedure is followed at the node  $x_{i+1}$ . Here, once again a central difference type discretization is employed as in Eq. (28) by enclosing the nodes  $x_{i+\theta}$ ,  $x_{i+1}$ , and  $x_{i+2}$ . In this case,  $p_{i+\theta}^+$  needs to be approximated by the means Lagrange polynomial interpolation. At the boundary  $\partial\Omega$ , pressure is computed by solving the zero pressure gradient condition:

$$\nabla p \cdot \hat{n} = 0 \quad (35)$$

$\hat{n}$  being a unit normal to the boundary. The values of  $p$  arising out of the Neumann boundary condition (35) are approximated by a fifth order one sided formula (see Anderson et al. (1984)). For example, on the right boundary (denoted by the index  $b$ ), the following backward difference formula is enforced:

$$p_{b,j} = \frac{1}{25} [48p_{b-1,j} - 36p_{b-2,j} + 16p_{b-3,j} - 3p_{b-4,j}] + O(h^5)$$

and likewise on the other three boundaries.

### 3.2 Time step

The time step,  $\Delta t$  must adhere to the CFL condition at each iteration due to the presence of convective terms. Therefore, the following restriction is imposed (Gutiérrez et al., 2018):

$$\Delta t \leq \min_{\Omega} \left\{ \frac{h}{\| \mathbf{u}^n \|}, \frac{h^2 \rho^n}{\mu^n}, \left( \frac{\rho_1 + \rho_2}{4\pi\sigma} \right)^{1/2} h^{3/2} \right\} \quad (36)$$

### 3.3 Calculation algorithm

This section summarizes how the solution algorithm proceeds iteratively to advance the solution of velocity field, pressure field, and level set function forward from time step  $t^n$  to  $t^{n+1}$ :

1. Calculate  $\Delta t$  (Section 3.2).
2. Compute  $\mathbf{u}^*$  from  $\mathbf{u}^n$  (Eq. (25)).
3. Solve the pressure Poisson equation (26) to calculate  $p$  (Section 3.1).
4. Compute  $\mathbf{u}^{n+1}$  from  $\mathbf{u}^*$  (Eq. (27)).
5. Solve the level set evolution equation (8) to advect  $\phi$  by using  $\mathbf{u}^{n+1}$ .
6. Iterate the reinitialisation equation (9) to correct  $\phi$  (Section 2.1).

7. Return to Step 1 till  $t > t_{\text{final}}$ .

## 4 Numerical examples

In order to affirm the validity and efficiency of the proposed methodology, a series of numerical experiments are conducted on flows involving simple and intricate interface geometries. Precisely, the following problems are addressed: circular flow with a fixed interface geometry to test the N–S solver; problem of the dispersion of capillary waves for validation and finally, transient evolution of initial circular, ellipse and star shaped bubbles to equilibrium static shapes. All the computations are performed on a laptop with i5-2430M processor with 4 GB RAM using a double precision floating point arithmetic on grid sizes ranging from  $20 \times 20$  to  $320 \times 320$ . The performance of our methodology is evaluated in terms of the infinity norm of the errors in velocity,  $\| \mathbf{u} \|_\infty$  and pressure,  $\| p \|_\infty$  such that  $\| \mathbf{u} \|_\infty = \sqrt{\frac{\| \mathbf{u} \|_\infty + \| \mathbf{v} \|_\infty}{2}}$ .

### 4.1 Circular flow

In order to ascertain the accuracy of the proposed methodology to solve N–S equations, an example with a fixed circular interface is chosen (Tan et al., 2008), which admits the exact solution:

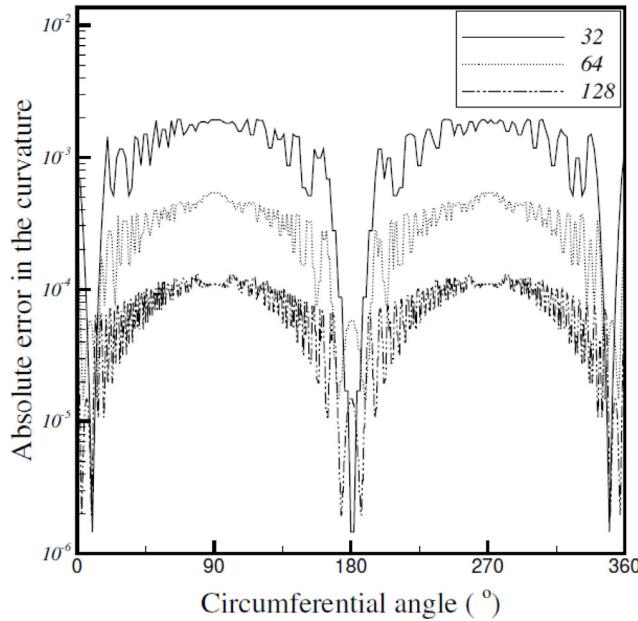

$$u(x, y, t) = \begin{cases} (1 - e^{-t}) \left( \frac{y}{r} - 2y \right), & \text{if } \phi > 0 \\ 0, & \text{if } \phi \leq 0 \end{cases}$$

$$v(x, y, t) = \begin{cases} (1 - e^{-t}) \left( \frac{-x}{r} + 2x \right), & \text{if } \phi > 0 \\ 0, & \text{if } \phi \leq 0 \end{cases}$$

$$p(x, y, t) = \begin{cases} \sin(\pi x) \sin(\pi y), & \text{if } \phi > 0 \\ 0, & \text{if } \phi \leq 0 \end{cases}$$

Here  $r = \sqrt{x^2 + y^2}$  and the interface is a circle centered at origin with radius 0.5 in a square computational domain of size  $[-1, 1] \times [-1, 1]$  with an equal grid spacing,  $h$ . Dirichlet boundary conditions are used at the outer boundaries.

Figure 3 plots the variation of absolute error in the curvature along the circumferential angle,  $0^\circ$  to  $360^\circ$  of the interface computed by using the formula given in Eq. (11). It is intended to verify the accurate calculation of curvature by considering three different grids:  $32 \times 32$ ,  $64 \times 64$ , and  $128 \times 128$ . Minimal error of order ranging from  $O(10^{-6})$  to  $O(10^{-3})$  is reported. It is noteworthy to mention that all the numerical results presented hereafter are simulated by using the numerical approximation to the curvature in Eq. (11). In order to affirm the adequateness of different grid sizes tested, Table 1 shows errors in velocity,  $\| \mathbf{u} \|_\infty$  and

**Fig. 3** Absolute error in the computed curvature along the circumferential angle,  $0^\circ$  to  $360^\circ$  of the interface for three different grids,  $32 \times 32$ ,  $64 \times 64$ , and  $128 \times 128$ .

**Table 1** Comparison of the errors in the dimensionless velocity,  $\| \mathbf{u} \|_\infty$  and pressure,  $\| p \|_\infty$  on grid refinement with the method proposed in Tan et al. (2008)

$n$	$\  \mathbf{u} \ _\infty$		$\  p \ _\infty$	
	Present	Tan et al. (2008)	Present	Tan et al. (2008)
32	$1.224 \times 10^{-3}$	$1.915 \times 10^{-3}$	$6.760 \times 10^{-3}$	$7.516 \times 10^{-3}$
64	$3.286 \times 10^{-4}$	$4.498 \times 10^{-4}$	$1.502 \times 10^{-3}$	$2.110 \times 10^{-3}$
128	$8.882 \times 10^{-5}$	$1.101 \times 10^{-4}$	$4.016 \times 10^{-4}$	$6.103 \times 10^{-4}$
256	$1.211 \times 10^{-5}$	$2.811 \times 10^{-5}$	$9.616 \times 10^{-5}$	$1.681 \times 10^{-4}$

pressure,  $\| p \|_\infty$  for  $\mu_2 = 1$ ,  $\mu_1 = 0.1$  at  $t = 2$  and compares them with the results of method proposed in Tan et al. (2008). It can be seen that our computed results are relatively better which certainly confirms the efficiency of the proposed methodology.

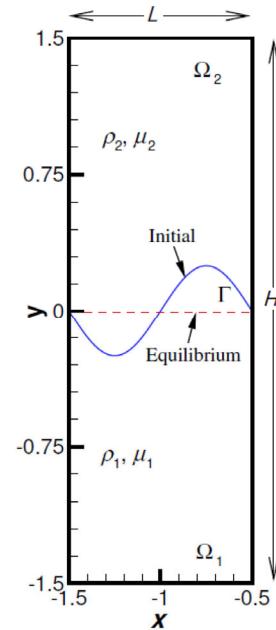

#### 4.2 Dispersion of capillary waves

The preceding test example permits us to predict the accurateness in the calculation of curvature and the performance of N-S solver. In the present example of capillary waves (Prosperetti, 1981; Popinet, 2009; Denner et al., 2017; Ge et al., 2018), the performance of the full methodology, i.e., coupling amongst the curvature calculation, N-S solver, and interface advection is validated. The problem of small amplitude oscillations associated with an initially sinusoidal interface between two superimposed viscous, incompressible fluids of infinite depth and lateral extent is addressed. A sinusoidal perturbation is induced to a horizontal interface

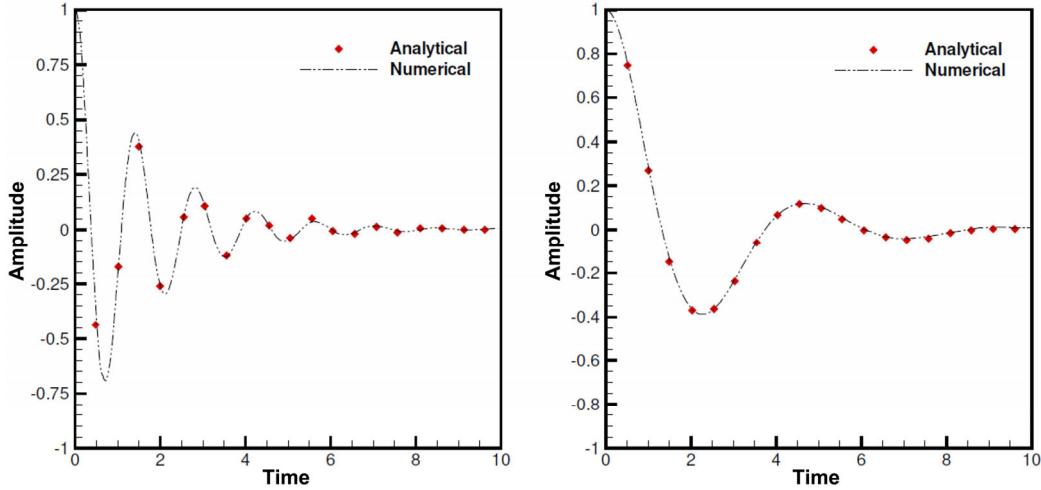

between two fluids initially at rest. Figure 4 sketches the interface configurations at initial and equilibrium states in a rectangular domain of length,  $L$  and height,  $H$ . The balance amongst surface tension, inertia, and viscosity leads to the oscillations of the interface around its equilibrium position. Numerical simulations are performed on an equally spaced grid of size  $64 \times 190$  on  $\Omega = [-1.5, 0.5] \times [-1.5, 1.5]$  with a time step,  $\Delta t = 1 \times 10^{-4}$ . The initial wavelength of the wave is chosen as  $\lambda = 1$  with an initial amplitude,  $a_0 = 0.1$ . The kinematic viscosities of both the fluids are assumed to be the same. Gravitational forces are assumed to be absent and flow regime is set by treating the horizontal walls as no slip boundaries and vertical walls as periodic boundaries. The following non dimensional parameters are adopted:  $\rho_1/\rho_2 = 100, 1000$ ;  $Re = 100$ ,  $We = 1$ . Figure 5 sketches the transient variation of interface curves in terms of the time evolution of their respective normalized amplitudes, computed on  $64 \times 190$  grid. The decay of oscillations is apparent from the clear fluctuations of amplitude curves in this figure. The numerical solution agrees well with the analytical solution of Prosperetti (1981), which certainly confirms the accurateness and efficiency of the proposed methodology.

#### 4.3 Static bubble

The present example addresses the problem of a stationary circular bubble in static equilibrium without gravity (Tong and Wang, 2007; Mier-Torrecilla et al., 2011; Hysing, 2012; Chakraborty et al., 2013; Balcázar et al., 2016). In the absence of viscous, gravitational or external forces, the circular

**Fig. 4** Illustration of interface configurations at initial and equilibrium states in computational domain.

**Fig. 5** Comparison of the transient evolution of the normalized amplitudes of capillary waves for (a)  $\rho_1 / \rho_2 = 10$  and (b)  $\rho_1 / \rho_2 = 100$ , with analytical solution of Prosperetti (1981), plotted on  $64 \times 190$  grid.

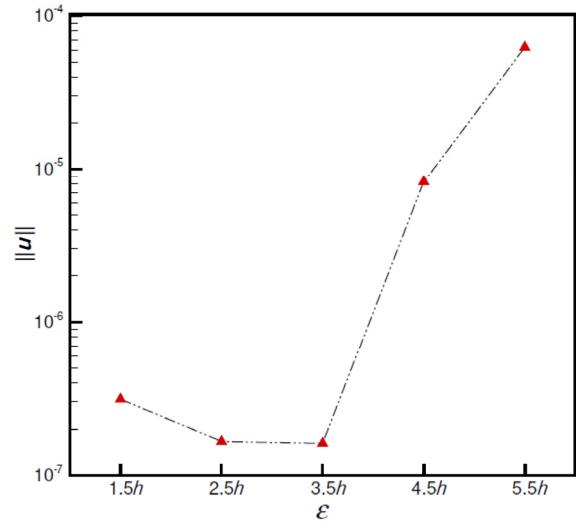

interface with surface tension should remain motionless with a pressure jump at the interface. This implies an exact equilibrium between the surface tension force and pressure gradient. Therefore, the analytical solution is a zero velocity field and a constant pressure jump at the interface, according to Young–Laplace condition, expressed as

$$[p]_{\text{exact}} = \sigma \kappa_{\text{exact}} \quad (37)$$

Here, the exact curvature is given by  $\kappa_{\text{exact}} = 1/r$  such that  $r$  is the radius of the bubble. The pressure field arises from a constant value  $p_{\text{out}} = p_0$  outside the bubble to a value  $p_{\text{in}} = p_0 + \sigma \kappa_{\text{exact}}$  inside the bubble. The pressure inside the bubble,  $p_{\text{in}}$  corresponds to the maximum pressure in  $\Omega$ , and the pressure outside the bubble,  $p_{\text{out}}$  corresponds to the minimum pressure in  $\Omega$ .

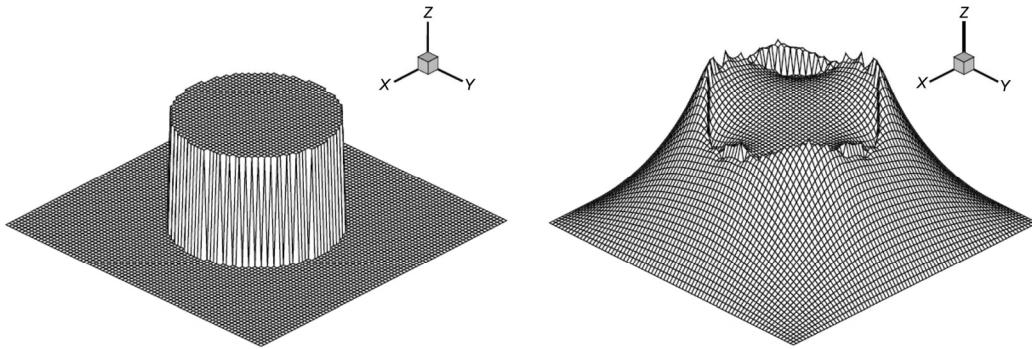

A bubble with radius  $r = 0.5$  is positioned in the center of a square domain,  $\Omega$  of size  $[-1,1] \times [-1,1]$ . No-slip conditions are imposed everywhere on the boundary of  $\Omega$ . The coefficients of surface tension, the density, and the viscosity inside and outside the bubble are all set to unity. This corresponds to a Weber number of  $We = 1$  and Reynolds number of  $Re = 1$ . However, circulating flow near the interface, known as spurious velocity currents arises because at a discretized level, accurate calculation of curvature and the balance between interfacial tension and pressure jump are not trivial problems (Connington and Lee, 2012). In the computational results that follow, these spurious currents are measured by errors in the dimensionless velocity,  $\|u\|_\infty$ .

Initially, in Fig. 6, we probe the influence of interface thickness,  $\varepsilon$  on the computed results in order to check the numerical diffusion in the transition zone,  $|\phi| \leq \varepsilon$ . A careless choice of  $\varepsilon$  could lead to an inappropriate shift in the zone of surface tension force (Chakraborty et al., 2013).

**Fig. 6** Effect of interface thickness,  $\varepsilon$  on the infinity norm of the error in velocity,  $\|u\|_\infty$ , computed on  $80 \times 80$  grid.

Figure 6 sketches the plots of errors in the dimensionless velocity for different values of  $\varepsilon$ , computed on a  $80 \times 80$  grid, at time,  $t = 10$ . The spurious currents reduce to  $O(10^{-6})$  when  $2.5h \leq \varepsilon \leq 3.5h$  and they rise thereafter. This suggests that the interface thickness has an influence on spurious currents, which are relatively strong when  $\varepsilon \geq 3.5h$  and as such,  $\varepsilon = 2.5h$  is chosen in our computations. Figure 7 sketches the pressure distribution on the whole domain,  $\Omega$  and absolute error between the numerical pressure and exact pressure, computed on  $80 \times 80$  grid. As expected, a piecewise constant pressure distribution in inner and outer domains is observed. No oscillation in the pressure profile resulting from this computation is seen near the interface as against some reported in the literature (Mier-Torrecilla et al., 2011; Balcázar et al., 2016). Figure 7(b) reports maximum error near the interface which is attributed to the numerical

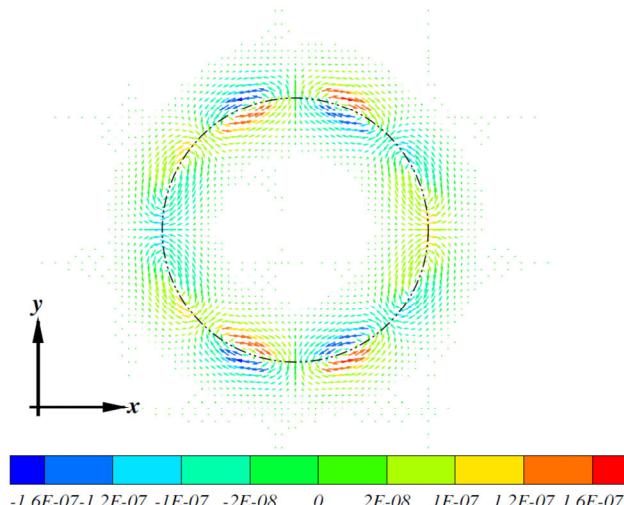

**Fig. 7** (a) Pressure distribution and (b) absolute error between the numerical pressure and exact pressure on the whole domain,  $\Omega$  computed on  $80 \times 80$  grid.

approximation of pressure due to jump discontinuity at the interface. Table 2 further consolidates how well the computed pressure fulfills Young–Laplace’s law as reflected by the infinity norm,  $\| p \|_\infty$ . One can clearly see that, for both pressure and velocity, the norm decreases rapidly with grid refinement, to converge with nearly second order accuracy. Figure 8 shows a typical distribution of spurious velocity currents around the interface, computed on a  $80 \times 80$  grid. Remarkably, the magnitude is  $O(10^{-7})$  which is lower than those reported by the methods proposed in Mier-Torrecilla et al. (2011).

**Table 2** Errors in the dimensionless velocity,  $\| u \|_\infty$  and pressure,  $\| p \|_\infty$  with their respective orders of accuracies with grid refinement

$n$	$\  u \ _\infty$	Order	$\  p \ _\infty$	Order

40	$5.814 \times 10^{-7}$	1.85	$6.680 \times 10^{-3}$	1.93
80	$1.615 \times 10^{-7}$		$1.758 \times 10^{-3}$	

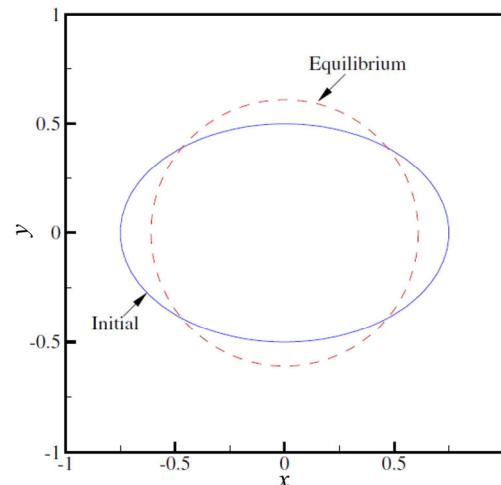

**Fig. 8** Spurious velocity currents around the bubble interface in terms of velocity vectors, plotted on  $80 \times 80$  grid.

#### 4.4 Oscillating bubble

In the present section, the problem of an initially non-spherical viscous bubble with subsequent oscillating decay to equilibrium circular shape is addressed (LeVeque and Li, 1997; Li and Lai, 2001; Li and Lubkin, 2001; Francois et al., 2006; Xu and Wang, 2006; Tong and Wang, 2007; Tan et al., 2008; Uh and Xu, 2012). The transient motion and evolution of the bubble till numerical equilibrium is analyzed in order to evaluate the performance of proposed methodology. Two different initial interface configurations: ellipse and star shaped are considered.

##### 4.4.1 Ellipse shaped interface

First, an initial ellipse shaped bubble with semi-major axis and semi-minor axis,  $r_x = 0.75$  and  $r_y = 0.5$  respectively, placed in the center of  $\Omega$  is considered. The interface configurations at initial and equilibrium states are sketched in Fig. 9. The bubble tends to acquire a circular shape at equilibrium with radius  $r_e \approx 0.61237$  (labeled as equilibrium in Fig. 9). We begin with the detailed discussion of the

**Fig. 9** Illustration of interface configurations at initial and equilibrium states in computational domain.

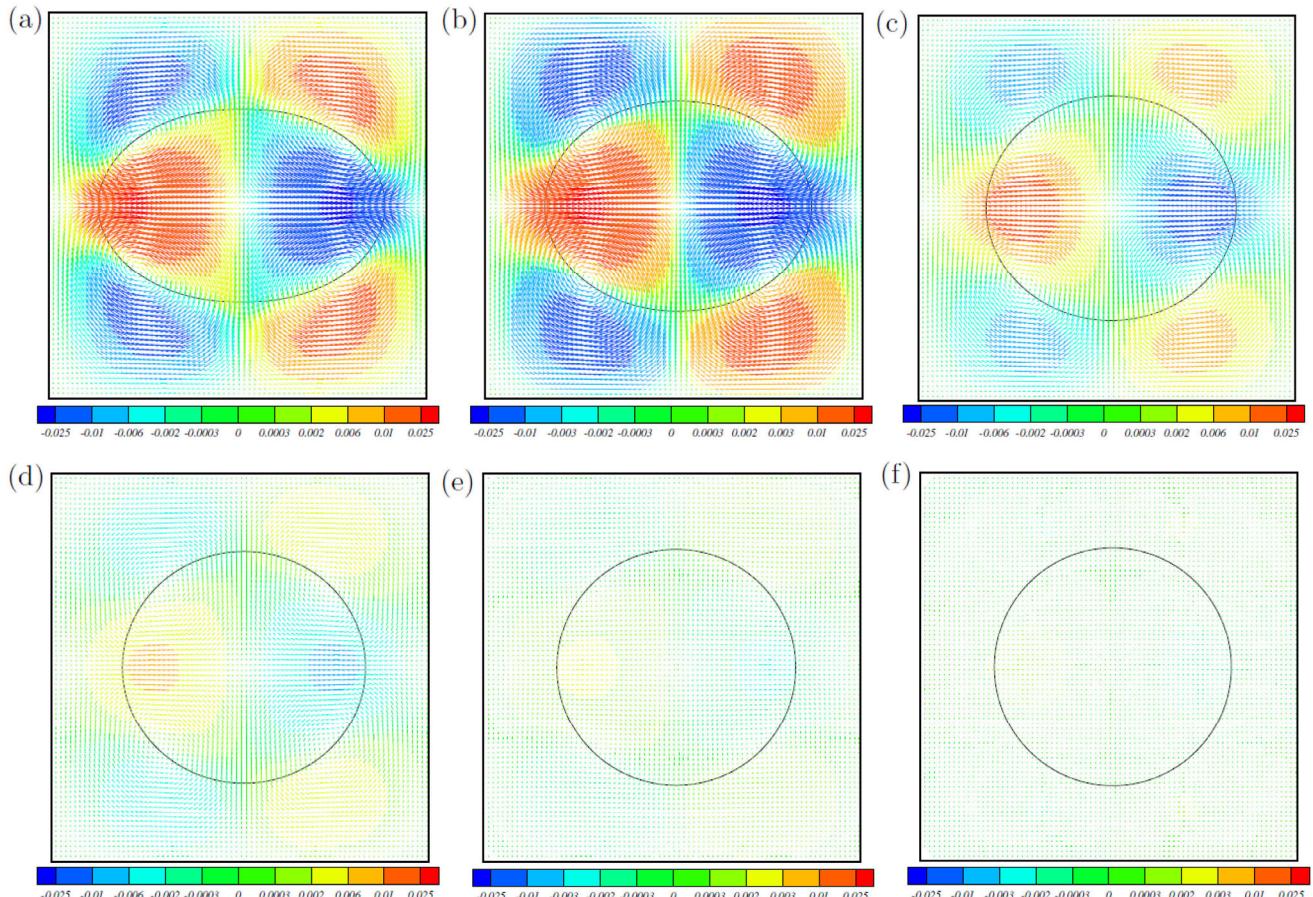

performance of our scheme using following non-dimensional parameters:  $\rho_1 = \rho_2 = 1$ ,  $\mu_1 = \mu_2 = 0.1$ ,  $Re = 10$ , and  $We = 10$ . Then, the performance is evaluated by reducing the value of  $We$  to 1. Firstly, a grid refinement analysis is performed to analyze the order of accuracy with the results of finest grid,  $320 \times 320$  chosen as reference value. Table 3 compiles the grid refinement analysis at  $t = 0$ , where the errors are measured in infi norm. One can easily see both velocity and pressure errors decaying at a rate of nearly  $O(h^2)$ . Figure 10 shows the transient oscillations of the

**Table 3** Errors in the dimensionless velocity,  $\| \mathbf{u} \|_\infty$  and pressure,  $\| p \|_\infty$  with their respective orders of accuracies on grid refinement at time  $t = 0$

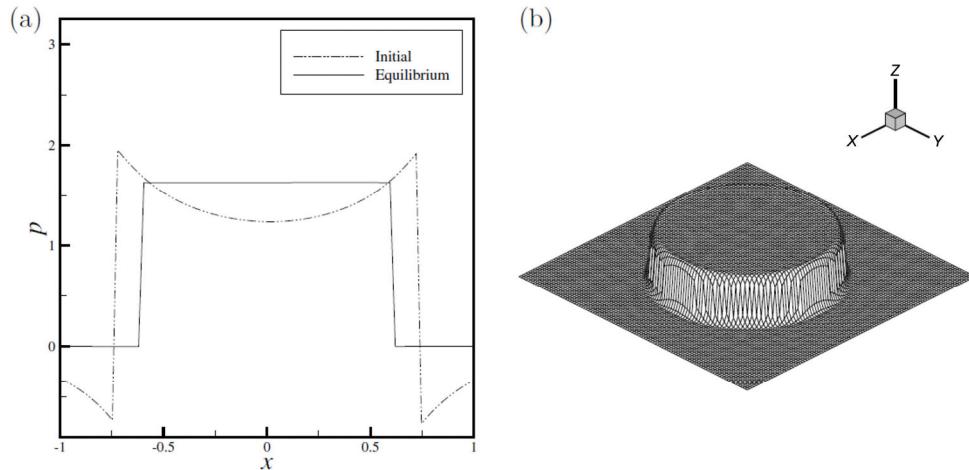

$n$	$\  \mathbf{u} \ _\infty$	Order	$\  p \ _\infty$	Order
40	$1.291 \times 10^{-2}$	1.96	$2.237 \times 10^{-2}$	1.76
80	$3.322 \times 10^{-3}$	2.01	$6.580 \times 10^{-3}$	1.84
160	$8.263 \times 10^{-4}$		$1.827 \times 10^{-3}$	

bubble and their profiles in terms of velocity vectors at time  $t = 0.5, 2.5, 5.0, 7.0, 10.0$ , and  $15.0$  for  $Re = 10$  and  $We = 10$ . The maximum velocity magnitudes first increase till time  $t = 2.5$  up to  $O(10^{-2})$  and then decrease up to  $O(10^{-4})$  till  $t = 15$ . Figure 11(a) sketches the transient evolution of pressure along the bubble centerline at initial and equilibrium states, computed on  $160 \times 160$  grid. As expected a piece-wise constant pressure distribution is observed in the inner and outer domains at the equilibrium circular shape. The pressure distribution over the whole domain is illustrated in Fig. 11(b). The pressure profile clearly exhibits no oscillations near the interface as against reported by few (Hysing, 2012; Balcazar et al., 2016). The numerical equilibrium is found to agree well with the true equilibrium using the proposed methodology. For instance, at  $t = 15$ , the error between  $r_x$  and  $r_e$  is only  $3.12e - 4$  and the error between  $r_y$  and  $r_e$  is only  $2.30e - 4$ . Further, the absolute error in area is  $5.33e - 4$  which indicates fairly little leakage of about 0.01%.

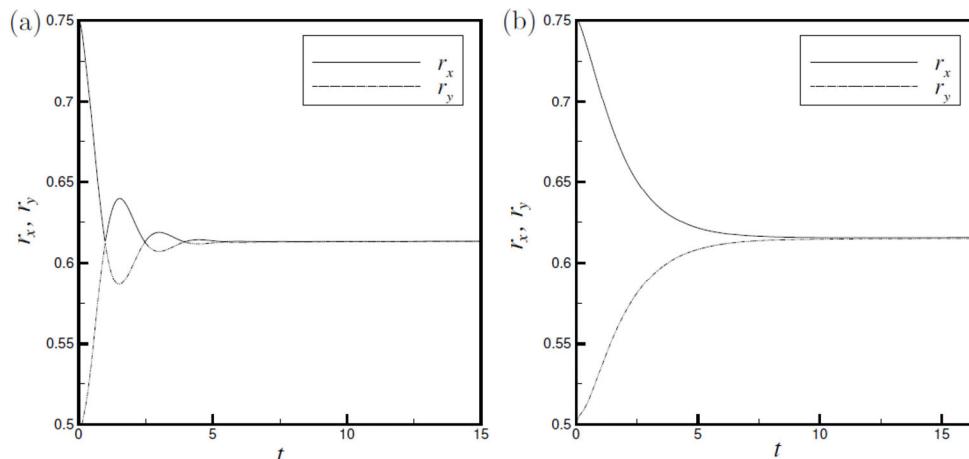

The transient variation of bubble shapes is further evaluated in terms of the time evolution of  $r_x$  and  $r_y$ . The evolution of  $r_x$  and  $r_y$  is plotted in Fig. 12 for different values

**Fig. 10** Transient oscillations of the bubble and their velocity profiles at time  $t =$  (a) 0.5, (b) 2.5, (c) 5.0, (d) 7.0, (e) 10.0, and (f) 15.0 for  $\rho_1 / \rho_2 = 1$ ,  $\mu_1 / \mu_2 = 1$ ,  $Re = 10.0$ , and  $We = 10.0$ .

**Fig. 11** (a) Transient evolution of pressure along the bubble centerline at initial and equilibrium states and (b) distribution of numerical pressure over the whole domain,  $\Omega$ , at equilibrium for  $\rho_1 / \rho_2 = 1$ ,  $\mu_1 / \mu_2 = 1$ ,  $Re = 10$ , and  $We = 10$ , computed on  $80 \times 80$  grid.

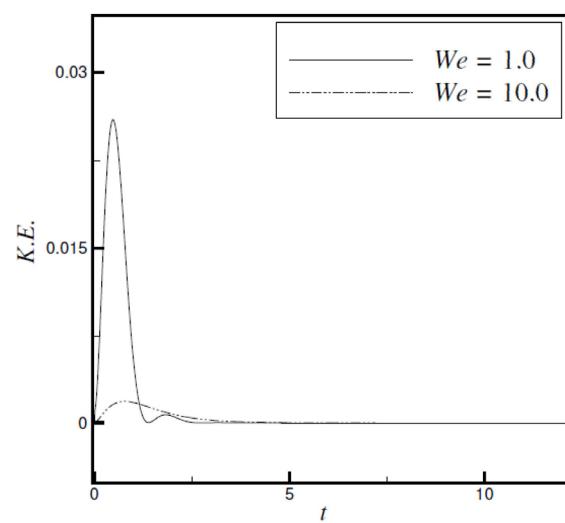

**Fig. 12** Transient evolution of the semi-major axis,  $r_x$  and semi-minor axis,  $r_y$  for (a)  $We = 1$  and (b)  $We = 10$  when  $\rho_2 / \rho_1 = 1$ ,  $\mu_2 / \mu_1 = 1$ , and  $Re = 10$ , computed on  $160 \times 160$  grid.

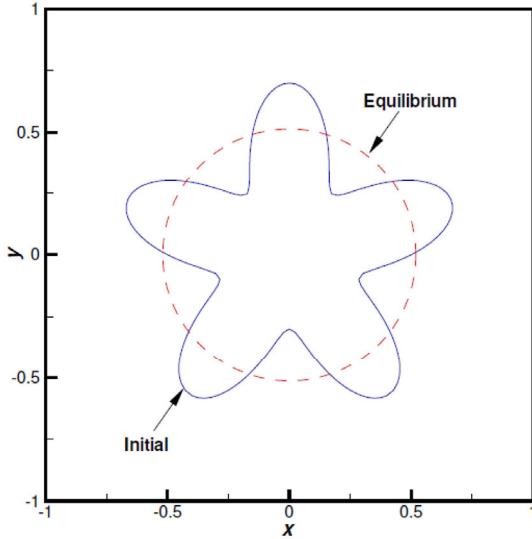

of  $We$  in order to analyze the effect of surface tension. The decay of oscillations is apparent from the clear fluctuating pattern of  $r_x$  and  $r_y$  in these figures. Further, it can be noticed that increase in the value of  $We$  reduces the motion of the bubble, which is reflected in fewer number of oscillations with smaller amplitudes and longer time to converge to equilibrium. This observation is further supported by the transient evolution of total kinetic energy,  $K.E. = \frac{1}{2} \int \rho \mathbf{u} \cdot \mathbf{u} d\mathbf{v}$ , sketched in Fig. 13. All these observations certainly confirm the accurateness and capability of the proposed methodology in simulating surface tension driven interfacial flows.

#### 4.4.2 Star shaped interface

In the final example, we illustrate the usefulness of proposed methodology to model surface tension effects in the vicinity of high curvature, complicated interface (star-shaped) geometry in the benchmark test. Figure 14 sketches the

**Fig. 13** Transient evolution of total kinetic energy for  $We = 1$  and  $We = 10$  when  $\rho_2 / \rho_1 = 1$ ,  $\mu_2 / \mu_1 = 1$ ,  $Re = 10.0$ , computed on  $160 \times 160$  grid.

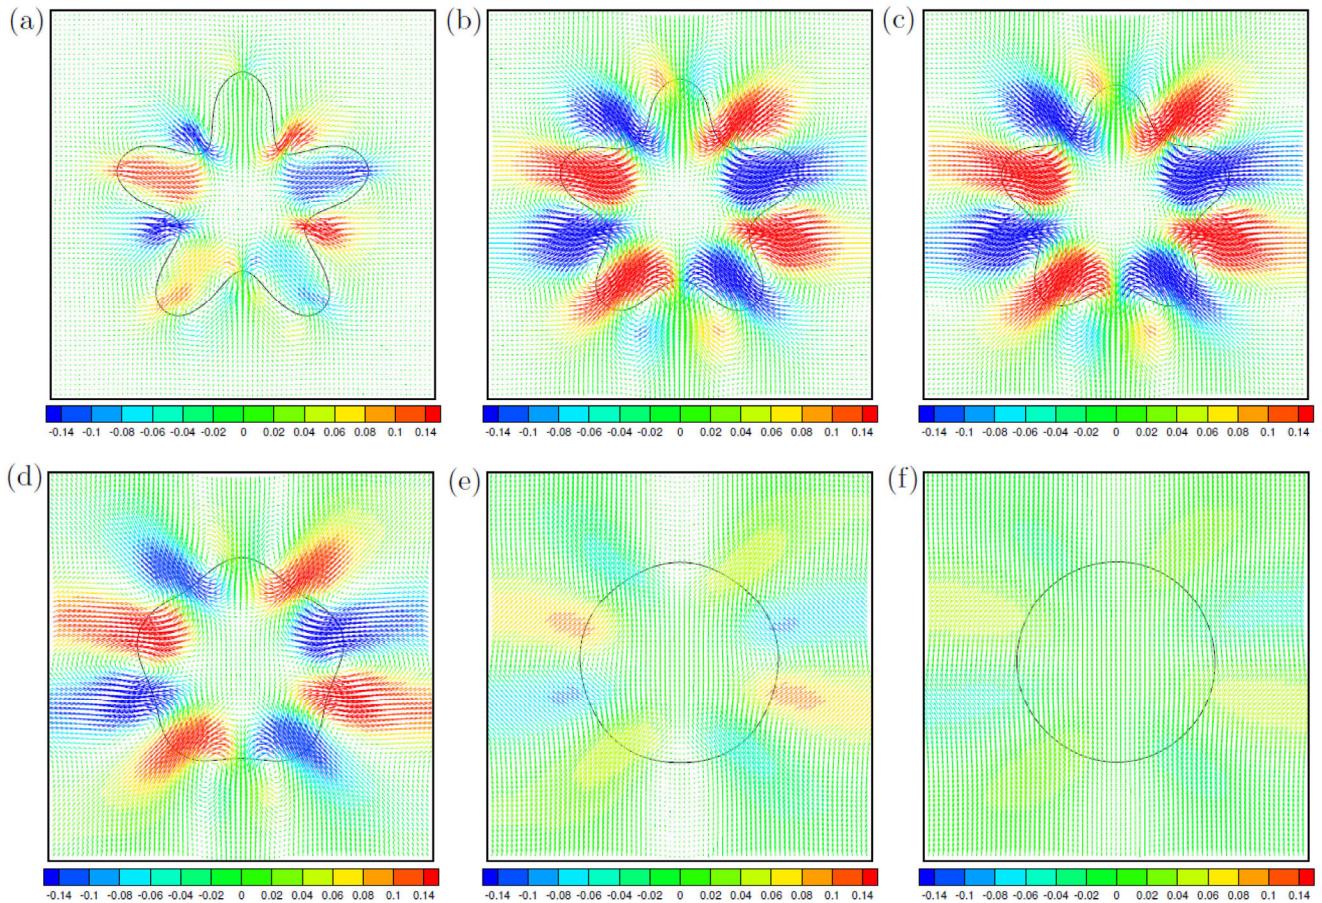

**Fig. 14** Illustration of interface configurations at initial and equilibrium states in computational domain.

interface configurations at initial and equilibrium states where the initial shape is defined in cylindrical coordinates  $(r, \theta)$  as

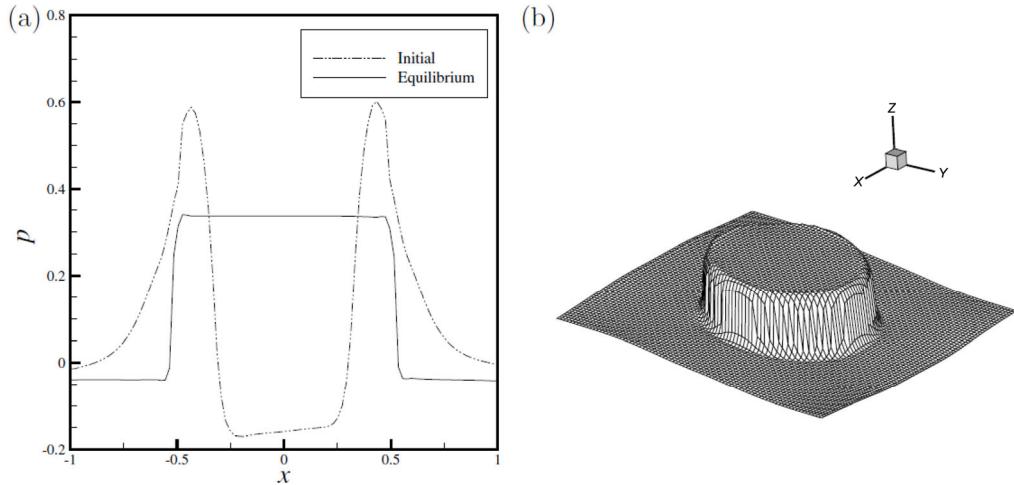

$$r(\theta) = r_0(1 + \varepsilon \sin(\zeta\theta)), \quad 0 \leq \theta \leq 2\pi$$

The bubble tends to converge to an equilibrium circular shape due to the effects of surface tension.

Flow regime is set by adopting the following non-dimensional parameters:  $\rho_1 = \rho_2 = 1$ ,  $\mu_1 = \mu_2 = 1$ ,  $Re = 1$ , and  $We = 10$ . Figure 15 sketches transient oscillations of the bubble shapes and their velocity profiles at time  $t = 0.5, 2, 7, 10, 14$ . The maximum velocity magnitudes first rise till time  $t = 5$  up to  $O(10^{-1})$  and then fall up to  $O(10^{-4})$  till  $t = 16$ . Figure 16(a) sketches the transient evolution of pressure along the bubble centerline at initial and equilibrium states, computed on  $160 \times 160$  grid. As expected a piece-wise constant pressure distribution is observed in the inner and outer domains at the equilibrium circular shape. The pressure distribution over the whole domain is illustrated in Fig. 16(b). The pressure profile clearly exhibits negligible oscillations near the interface which proves the capability of our scheme in efficiently resolving the pressure jump in the vicinity of complex, high curvature interfaces as well. Table 4 shows grid refinement analysis of error infinity norm of our computed results. The infinity norm of error in the solution

**Fig. 15** Transient oscillations of the bubble and their velocity profiles at time  $t = 0.5, 2, 7, 10, 14$ , and 16 for  $\rho_1 = \rho_2 = 1$ ,  $\mu_1 = \mu_2 = 1$ ,  $Re = 1$ , and  $We = 20$ .

**Fig. 16** (a) Time evolution of pressure along the centerline at time  $t = 0.5, 2.5, 5.0, 7.0, 10.0$ , and  $15.0$ , and (b) distribution of numerical pressure over the whole domain,  $\Omega$  at  $t = 15$  for  $\rho_1 / \rho_2 = 1$ ,  $\mu_1 / \mu_2 = 1$ ,  $Re = 10$ , and  $We = 10$ , computed on  $180 \times 180$  grid.

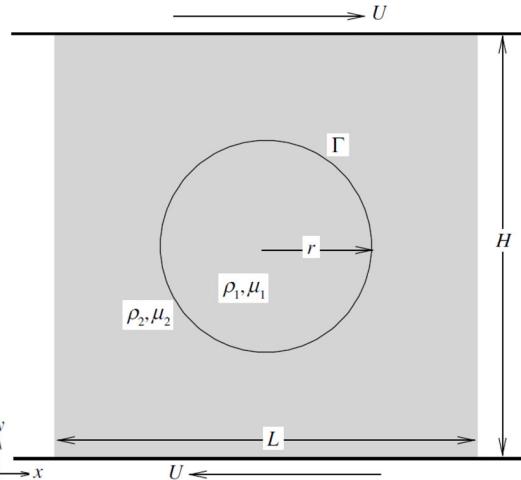

**Table 4** Errors in the dimensionless velocity,  $\| \mathbf{u} \|_\infty$  and pressure,  $\| p \|_\infty$  with their respective orders of accuracies with grid refinement at time  $t = 0$

$n$	$\  \mathbf{u} \ _\infty$	Order	$\  p \ _\infty$	Order
40	$1.486 \times 10^{-2}$	1.89	$3.421 \times 10^{-2}$	1.95
			$8.832 \times 10^{-3}$	
80	$4.026 \times 10^{-3}$	2.03	$2.226 \times 10^{-3}$	1.98

is small and the accuracy does not seem to be affected by arbitrary shaped interface as long as grid resolution is high enough to allow for one sided interpolation. Moreover, one can easily see convergence rate near to second order for both the parameters.

#### 4.5 Deforming drops

In this subsection, the problem of a liquid drop implanted in another immiscible liquid subjected to shear flow is addressed. Figure 17 shows an illustration of square computational domain, containing a liquid drop, where upper and bottom walls move with opposite velocities thereby inducing a plane Couette flow. It is admitted from the literature that, in such flow configurations, the drop reciprocates by deforming and by developing an internal circulation in the direction of the flow (Sheth and Pozrikidis, 1995; Li et al., 2007; Farokhirad et al., 2013). In present computations, the radius of the drop is set to one fourth of the domain height,  $r = 0.25H$ , where  $L/H = 1$ . The physical properties of the fluids and surface tension,  $\sigma$  of the drop interface are assumed to be uniform and constant during the motion.

**Fig. 17** Illustration of a square computational domain of length,  $L$ , and height,  $H$ , containing a liquid drop of radius,  $r$ , such that both upper and bottom walls of the domain move with opposite velocities,  $\pm U$ .

Flow regime is set by treating the vertical walls as periodic boundaries and by adopting the following non dimensional parameters:  $Re = 100$  and  $Ca = 0.1, 0.2, 0.3, 0.4$ . The Capillary number,  $Ca = We/Re$ , represents the relative magnitude of viscous and capillary forces along the interface. The density and viscosity ratios are assumed to be unity. The transient variation of drop shapes is evaluated in terms of deformation parameter,  $D_{Df}$  expressed as

$$D_{Df} = \frac{r_x - r_y}{r_x + r_y}$$

The transient evolution of  $D_{Df}$  is plotted in Fig. 18(a) for different values of  $Ca$  in order to analyse the effect of surface tension. A first inspection reveals that increase in the value of  $Ca$  increases the magnitude of  $D_{Df}$ . Further, it

is noticed that, when  $Ca = 0.1$ ,  $D_{Df}$  tends to a constant value near time  $t = 2$  which signifies that the drop tends to acquire a steady shape. However, when  $Ca > 0.1$ ,  $D_{Df}$  continues to increase which signifies that the drop continues to elongate and does not acquire a stationary shape. Figure 18(b) sketches the contours of drop shapes at time  $t = 3$  for different values of  $Ca$ . When  $Ca = 0.1$ , the shape of the drop resembles an ellipse. However, for high values of  $Ca$  ( $Ca > 0.1$ ), the drops are exceptionally deformed and they display a significant deviation from a steady elliptic shape. Deliberately, the minor axis shortens and the major axis lengthens and consequently they tend to acquire a sigmoidal shape while rotating in clockwise direction. In order to investigate the structure of the flow inside and outside the drop, contour plots of streamline patterns are sketched in Fig. 19 for  $Ca = 0.1$  and  $0.4$ . The following Poisson equation for stream-function is solved to serve the purpose:

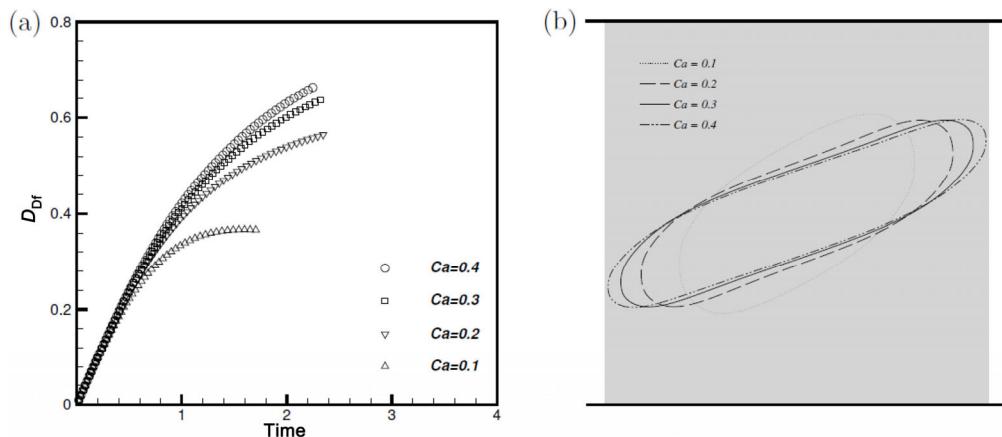

$$\Delta\psi = u_y - v_x$$

When  $Ca = 0.1$ , the drop interface is tangential to the local streamlines affirming that the drops have attained steady shapes. The drops are wrapped by dividing streamlines that

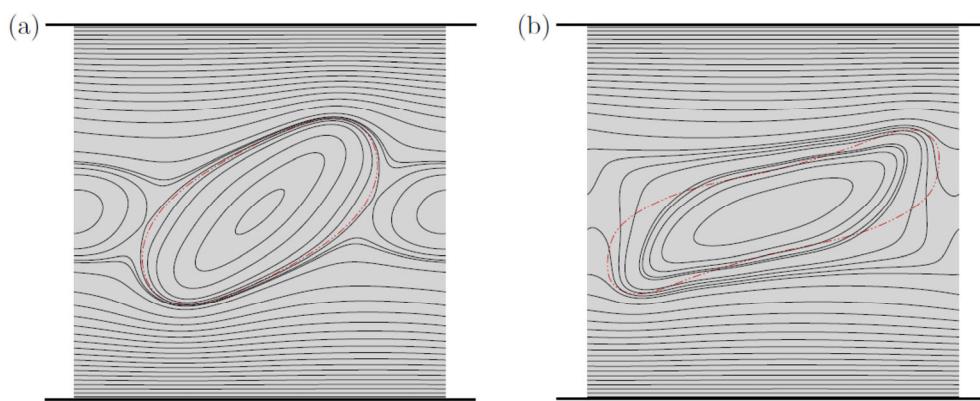

end at stagnation points positioned intermediary between drops and nearby the  $x$ -axis. However, when  $Ca = 0.4$ , the streamlines cross the drop interface demonstrating that drops continue to elongate and manage to rotate in clockwise direction due to the effect of the vorticity of the incoming flow. Next, in order to understand the inertial effects, Fig. 20 sketches the contours of drop shapes at time  $t = 2$  for  $Ca = 0.2$  and different values of  $Re = 10, 50, 80$ , and  $100$ . It can be seen that inertial flow plays a significant role in deciding equivalent drop shapes and drops turn out to elongate more with increasing  $Re$ . This points to the fact that an increase in  $Re$  leads to an easier deformation. All these observations are coherent with previous studies (Sheth and Pozrikidis, 1995; Farokhirad et al., 2013) which certainly confirm that the proposed methodology can strongly capture primary traits of drop deformation in shear flows.

## 5 Conclusions

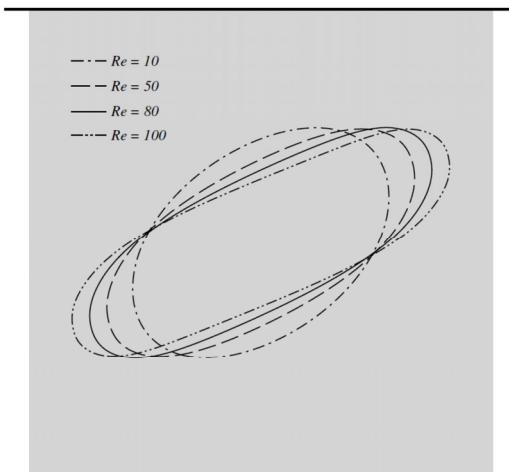

In this paper, a coupling between a novel immersed interface method and level set method is proposed to simulate surface tension driven interfacial flows. The proposed methodology

**Fig. 18** (a) Transient evolution of drop shapes in terms of deformation parameter,  $D_{Df}$ , and (b) contours of drop shapes at time  $t = 3$ ; for different values of  $Ca$  and  $Re = 100$ , computed on  $180 \times 180$  grid.

**Fig. 19** Contour plots of streamline patterns for (a)  $Ca = 0.1$  and (b)  $Ca = 0.4$ ;  $Re = 100$ , computed on  $180 \times 180$  grid.

**Fig. 20** Contours of drop shapes at time  $t = 2$  for  $Ca = 0.2$  and different values of  $Re$ , computed on  $180 \times 180$  grid.

highly simplifies the grid generation process as it permits us to use a uniform, fixed Cartesian grid. First, an example with a fixed circular interface is presented to predict the accurateness in the calculation of curvature and the performance of N-S solver. Next, the algorithm is validated by the comparing the results with analytical solution by simulating the problem of small amplitude oscillations associated with the dispersion of capillary waves. Finally, the problems of initially circular, ellipse shaped, and star shaped bubbles with an oscillating decay to a numerical equilibrium, and circular drops deforming in shear flows are addressed. The transient evolution of bubbles/drops in terms of their shapes, pressure profiles, velocity vectors, deformation ratios of major and minor axis is analyzed to observe the effect of surface tension. The methodology is shown to regain the exact numerical equilibrium between the surface tension and pressure gradient in the vicinity of high curvature interface geometries as well. It demonstrates accurate resolution of pressure nullifying the presence of any oscillations in the vicinity of the interface and Young-Laplace's law is validated to a good level of accuracy and with a significantly reduced spurious currents. Grid refinement analysis of the infinity error norms of pressure and velocities reports the convergence rates near to two for the test cases. Moreover, primary traits of physical behaviour of drop deformations in shear flows are strongly captured by the proposed methodology. Numerical results show that the proposed methodology yields a good level of agreement with the reference data. It is noteworthy to mention that the immersed interface method employed in the present computations has already been validated for a fixed interface in three dimensions (Mittal and Ray, 2018). This opens up a possibility of their extension to address the problems of moving interfaces in three dimensions, which is the objective of our next paper.
